

The Impact of Climate Change on Marine Ecosystems

Global warming is dramatically changing marine ecosystems worldwide. Increasing sea temperatures have caused extensive coral bleaching, which endangers the biological diversity of reef systems.

In addition, the acidification of oceans, resulting from greater uptake of atmospheric carbon dioxide, is weakening the shells of various marine organisms such as mollusks and certain plankton species.

Department of Environmental Science

Scientists have noted that fish migration patterns are moving toward colder waters in direct response to rising ocean temperatures. This change disrupts existing food webs and affects commercial fishing operations.
